Stationarity

Definition

- Stationarity refers to the **stability** of a sequence **over time**.
- A series is called stationary if its **statistical characteristics** do not change over time.
- Most **classic time-series models** (AR, MA, ARMA, ARIMA) assume the data is **stationary**.

Stationarity

Two common notions of stationarity:

- Strict Stationarity:
 - The entire distribution of the series is invariant over time
- Weak (Covariance) Stationarity
 - Mean is constant over time
 - Variance is constant over time
 - Autocovariance depends only on lag, not on time
- Most time-series models assume **weak stationarity**

Weakly Stationary Time Series
(constant mean and variance)

Non-Stationary Time Series
(changing mean or variance)

Stationarity

Two common notions of stationarity:

- In weak Stationarity:
 - Mean is constant over time
 - Variance is constant over time
 - Autocovariance depends **only on lag, not on time**

$$\mathbb{E}[X_t] = \mu, \quad \forall t$$

$$\text{Var}(X_t) = \sigma^2, \quad \forall t$$

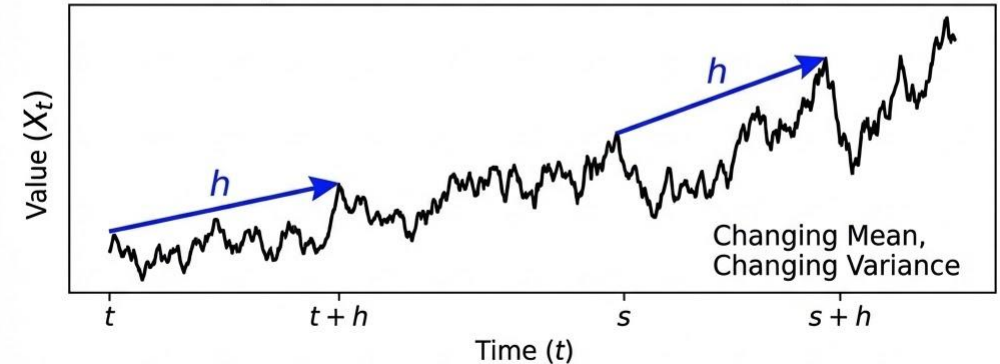

$$\text{Cov}(X_t, X_{t+h}) = \gamma(h)$$

Stationary Time Series (Autocovariance Depends Only on Lag h)

$$\text{Cov}(X_t, X_{t+h}) = \text{Cov}(X_s, X_{s+h}) = \gamma(h) \text{ for all } t, s$$

Non-Stationary Time Series (Autocovariance Changes Over Time)

$$\text{Cov}(X_t, X_{t+h}) \neq \text{Cov}(X_s, X_{s+h}) \text{ (Depends on both } t \text{ and } h)$$

Stationarity

Two common notions of stationarity:

Stationary Time Series

- Model: $x_t = \varepsilon_t$
- Constant mean: $\mu = 0$
- Constant variance: $\sigma^2 = 1$
- No trend over time

Non-Stationary Time Series

- Model: $x_t = 0.05t + \varepsilon_t$
- Mean changes over time
- Presence of deterministic trend
- Violates stationarity assumption

Stationary Time Series
($x_t = \varepsilon_t$)

Non-Stationary Time Series
($x_t = 0.05t + \varepsilon_t$)

Stationarity

Two common notions of stationarity:

- Based on the figure, which series is stationary and which is non-stationary?
- For each series, comment on:
 - Mean behavior over time
 - Variance behavior over time
- Propose **possible mathematical model** for each series.
- Which series violates the stationarity assumption required by AR / MA models? Explain why.

Stationarity

Two common notions of stationarity:

Question 1

Which series is stationary and which is non-stationary?

- Series A: Stationary
- Series B: Non-stationary

Question 2

Mean and variance behavior

Series A

- Mean: constant over time (≈ 0)
- Variance: constant
- Fluctuations are symmetric and stable

Series B

- Mean: changes over time (downward trend)
- Variance: approximately constant
- Presence of deterministic trend

Stationarity

Two common notions of stationarity:

Question 3

Possible mathematical models

- Series A:

$$x_t = \varepsilon_t, \quad \varepsilon_t \sim \mathcal{N}(0, 1)$$

- Series B:

$$x_t = -0.03t + \varepsilon_t, \quad \varepsilon_t \sim \mathcal{N}(0, 1)$$

Question 4

Which series violates stationarity and why?

- Series B violates stationarity
- Because:

$$\mathbb{E}[x_t] = -0.03t$$

depends explicitly on time

➡ Mean is not constant → non-stationary

Unit Root Tests

Why Do We Need Unit Root Tests?

- **Visual inspection** is not sufficient
- Some **non-stationary** series look stationary
- Unit root causes **persistent shocks**
- Formal statistical testing is required

Unit Root Tests

Why Do We Need Unit Root Tests?

- Review this figure:
 - Small amplitude of oscillation (low noise variance)
 - There is no clear trend in the short term.
 - Fluctuating around a "seemingly stable" level.
- However: This is a non-stationary series
 - Mathematical model

$$x_t = x_{t-1} + \varepsilon_t$$

- This is a **random walk**, with:
 - Unit root
 - Without string pull, the mean returns to zero.

Unit Root Tests

What Is a Unit Root?

- Consider an AR(1) process: $x_t = \phi x_{t-1} + \varepsilon_t$
- The process has a **unit root** if: $\phi = 1$
- In this case:

$$x_t = x_{t-1} + \varepsilon_t$$

- The series becomes a **random walk**
- Shocks have **permanent effects**
- Mean and variance are **not time-invariant**

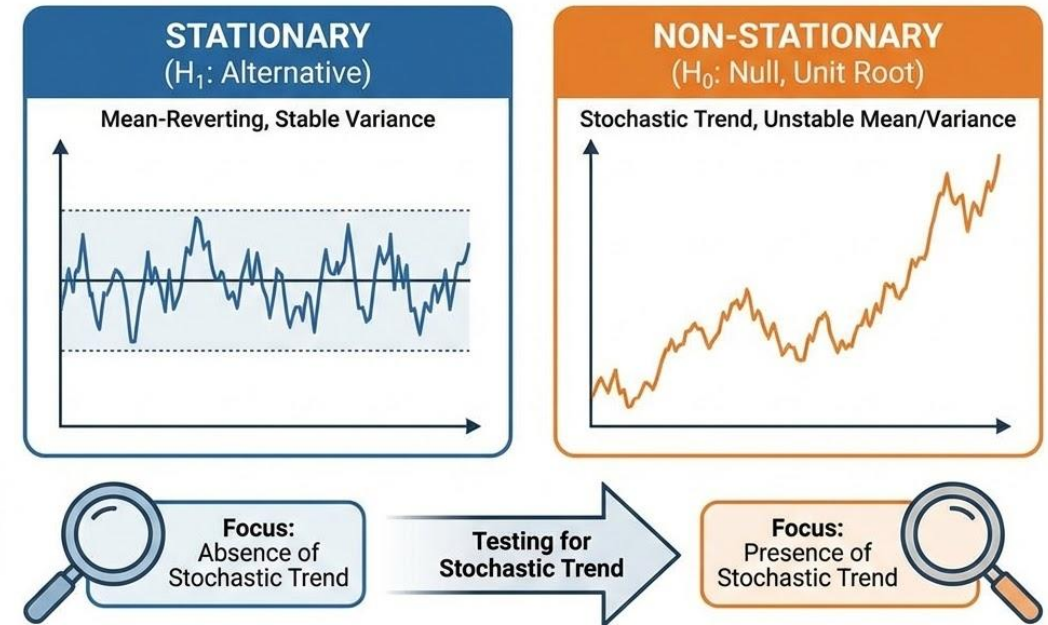

Unit Root Tests

What is being tested?

- Whether a time series is stationary or contains a unit root
- Focus on the stochastic trend in the data
- Hypotheses
 - Null hypothesis (H_0): The series has a unit root (non-stationary)
 - Alternative hypothesis (H_1): The series is stationary
- Common unit root tests
 - ADF (Augmented Dickey–Fuller)
 - KPSS (reverse hypothesis)

UNIT ROOT TESTS: Testing for Stationarity

HYPOTHESES & TESTS

Hypotheses (H_0 & H_1)	Common Unit Root Tests
H_0: Unit Root (Non-Stationary) - Series has a stochastic trend.	ADF (Augmented Dickey–Fuller) - Tests for H_0 (Unit Root).
H_1: Stationary - Series is mean-reverting.	KPSS (Kwiatkowski–Phillips–Schmidt–Shin) - Tests for H_0 (Stationarity) [Reverse Hypothesis].

Note: Tests evaluate the presence of a unit root, which indicates a non-stationary stochastic trend in the data.

Unit Root Tests

Augmented Dickey–Fuller (ADF) Test

Purpose

- Test whether a time series has a **unit root**
- Extension of the Dickey–Fuller test to handle **autocorrelation**

Test equation

$$\Delta y_t = \gamma y_{t-1} + \sum_{i=1}^p \alpha_i \Delta y_{t-i} + \varepsilon_t$$

Hypotheses

- $H_0: \gamma = 0 \rightarrow$ unit root (non-stationary)
- $H_1: \gamma < 0 \rightarrow$ stationary

Key idea

- Test the **significance of γ**
- Uses **non-standard critical values**

Where:

- Δy_t : first difference of the series
- y_{t-1} : lagged level (unit root term)
- γ : unit root coefficient (key parameter)
- Δy_{t-i} : lagged differences (augmentation terms)
- p : number of lags
- ε_t : white noise error

ADF intuition

Unit Root Tests

Augmented Dickey–Fuller (ADF) Test

$$\Delta y_t = \gamma y_{t-1} + \sum_{i=1}^p \alpha_i \Delta y_{t-i} + \varepsilon_t$$

Current state of the system
The level the series was at previously

“Augmented” part

$\Delta y_t = y_t - y_{t-1}$: *First-order difference of a series*

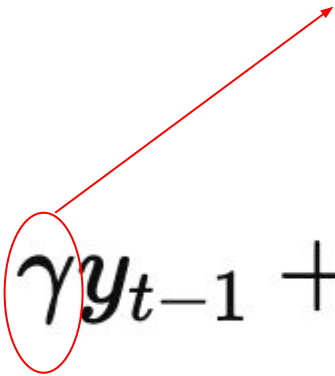

The diagram illustrates the Augmented Dickey–Fuller (ADF) test equation. The equation is $\Delta y_t = \gamma y_{t-1} + \sum_{i=1}^p \alpha_i \Delta y_{t-i} + \varepsilon_t$. Red circles highlight four components: Δy_t , y_{t-1} , the sum $\sum_{i=1}^p \alpha_i \Delta y_{t-i}$, and ε_t . Arrows point from these circles to explanatory text. The text for y_{t-1} is "Current state of the system" and "The level the series was at previously". The text for the sum is "“Augmented” part". A grey box below the equation defines $\Delta y_t = y_t - y_{t-1}$ as "First-order difference of a series".

Unit Root Tests

Augmented Dickey–Fuller (ADF) Test

Parameters to be tested

Answer the question: "When the trend is at a high, does it tend to reverse or continue further?"

$$\Delta y_t = \gamma y_{t-1} + \sum_{i=1}^p \alpha_i \Delta y_{t-i} + \varepsilon_t$$

- The entire ADF test only tests a single hypothesis: $H_0 : \gamma = 0$

- $\gamma = 0$: No pull-back → Random walk
- $\gamma < 0$: With pull-back → Mean-reverting
- $\gamma > 0$: Explosive sequence

Unit Root Tests

Augmented Dickey–Fuller (ADF) Test

```
from statsmodels.tsa.stattools import adfuller

def adf_test(timeseries):
    print("Results of Dickey-Fuller Test:")
    dfctest = adfuller(timeseries, autolag="AIC")
    dfcoutput = pd.Series(
        dfctest[0:4],
        index=[
            "Test Statistic",
            "p-value",
            "#Lags Used",
            "Number of Observations Used",
        ],
    )
    for key, value in dfctest[4].items():
        dfcoutput["Critical Value (%s)" % key] = value
    print(dfcoutput)
```

Results of Dickey-Fuller Test:

Test Statistic	-2.837781
p-value	0.053076
#Lags Used	8.000000
Number of Observations Used	300.000000
Critical Value (1%)	-3.452337
Critical Value (5%)	-2.871223
Critical Value (10%)	-2.571929
dtype:	float64

If ADF statistic < Critical Value → Reject H_0 (unit root)

Threshold provided by Dickey-Fuller

Unit Root Tests

KPSS Test (Kwiatkowski–Phillips–Schmidt–Shin)

- KPSS tests stationarity directly, not unit root.
- Whether a time series is stationary around a level or a trend.
- Hypotheses:
 - H_0 : The series is **stationary**
 - H_1 : The series is **non-stationary** (has unit root)
- Refer [code example](#)

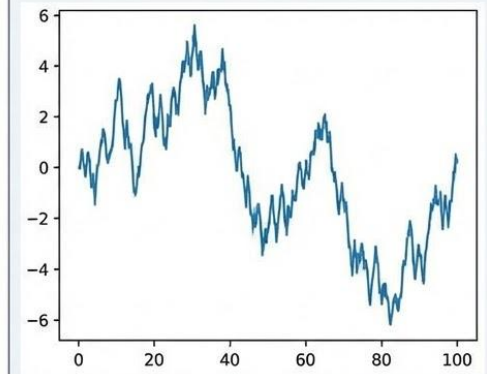

KPSS Test (Kwiatkowski–Phillips–Schmidt–Shin) for Stationarity

H_0 : Trend Stationary (Null Hypothesis)

Series is stationary around
a deterministic trend.

H_a : Unit Root (Non-Stationary) (Alternate Hypothesis)

Series has a unit root,
not stationary.

KPSS_test(time_series) → p-value
Function created to evaluate stationarity evidence.

- Stationarity
- Unit Root Test
- Differencing
- AR / MA / ARMA Models

Differencing

Differencing

Goal:

Remove unit root and make the series stationary.

First-order differencing:

$$\Delta y_t = y_t - y_{t-1}$$

Higher-order differencing:

$$\Delta^d y_t = (1 - L)^d y_t$$

Key idea:

- Differencing removes **stochastic trend**
- Transforms **non-stationary** → **stationary**

- Refer [code example](#)

- Differencing
- AR / MA / ARMA Models

AR / MA / ARMA Models

- After differencing, many time series become **stationary**
- Stationary series still exhibit **temporal dependence**
- AR / MA / ARMA models:
 - Capture **short-term memory**
 - Describe how the present depends on:
 - past values
 - past shocks
- They form the foundation of **ARIMA models**

AR / MA / ARMA Models

Autoregressive (AR) Model

- An AR model explains the current value of a time series using its **own past values**.
- The idea is that the series has **memory**: past observations influence the present.
- Suitable for **stationary** time series.

AR(p) model:

$$x_t = c + \sum_{i=1}^p \phi_i x_{t-i} + \varepsilon_t$$

Where:

- x_t : value at time t
- p : order of the AR model
- ϕ_i : autoregressive coefficients
- ε_t : white noise

AR / MA / ARMA Models

Autoregressive (AR) Model

```
from statsmodels.tsa.ar_model import AutoReg

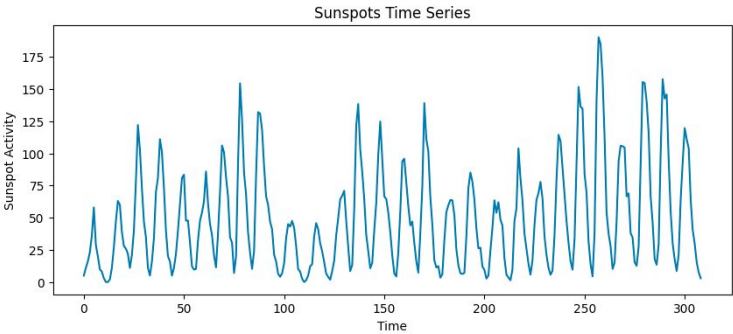

# train
model = AutoReg(ts_diff, lags=1)
result = model.fit()

print(result.summary())
```

AR / MA / ARMA Models

Moving Average (MA) Model

- An MA model explains the current value of a time series using **past error terms (shocks)**.
- The idea is that the series reacts to **unexpected disturbances**, not past values.
- Suitable for **stationary time series**.

MA(q) model:

$$x_t = \mu + \varepsilon_t + \sum_{i=1}^q \theta_i \varepsilon_{t-i}$$

Where:

- x_t : value at time t
- μ : mean of the series
- ε_t : white noise (random shock)
- q : order of the MA model
- θ_i : moving average coefficients

Moving Average (MA) Model

AR / MA / ARMA Models

Moving Average (MA) Model

```
from statsmodels.tsa.arima.model import ARIMA

# MA(q) is ARIMA(0, 0, q)
model = ARIMA(ts_diff, order=(0, 0, 1))
result = model.fit()

print(result.summary())
```

MA trong statsmodels = ARIMA(0,0,q)

Trong ARIMA:

- $p \rightarrow$ AR part
- $d \rightarrow$ differencing
- $q \rightarrow$ MA part

Do đó:

$MA(q) \equiv ARIMA(0,0,q)$

Nghĩa là:

- Không dùng giá trị quá khứ
- Không differencing
- Chỉ dùng q sai số quá khứ

AR / MA / ARMA Models

Autoregressive (AR) vs Moving Average (MA)

Aspect	AR Model	MA Model
Core idea	Uses past values	Uses past shocks
Memory	Long-term memory	Short-term memory
Mathematical form	$x_t = \sum \phi_i x_{t-i} + \varepsilon_t$	$x_t = \varepsilon_t + \sum \theta_i \varepsilon_{t-i}$
Dependency	Past observations	Past errors
Interpretation	Persistence	Shock absorption
Typical use	Trend-like persistence	Noise-like series
ACF pattern	Tails off	Cuts off
PACF pattern	Cuts off	Tails off
Stationarity required	Yes	Yes

Autoregressive (AR) Model

Present value connected to multiple past values (Memory Chain)

Moving Average (MA) Model

Present value formed by averaging past random shocks (Noise Signals)

Thank you
